## Abstract

Composition is a practice of key importance in software engineering. When real-time applications are composed it is necessary that their timing properties (such as meeting the deadlines) are guaranteed. The composition is performed by establishing an interface between the application and the physical platform. Such an interface does typically contain information about the amount of computing capacity needed by the application. In multiprocessor platforms, the interface should also present information about the degree of parallelism. Recently there have been quite a few interface proposals. However, they are either too complex to be handled or too pessimistic. In this paper we propose the Generalized Multiprocessor Periodic Resource model (GMPR) that is strictly superior to the MPR model without requiring a too detailed description. We describe a method to generate the interface from the application specification. All these methods have been implemented in Matlab routines that are publicly available.

## ABSTRACT

Composition is a practice of key importance in software engineering. When real-time applications are composed it is necessary that their timing properties (such as meeting the deadlines) are guaranteed. The composition is performed by establishing an interface between the application and the physical platform. Such an interface does typically contain information about the amount of computing capacity needed by the application. In multiprocessor platforms, the interface should also present information about the degree of parallelism. Recently there have been quite a few interface proposals. However, they are either too complex to be handled or too pessimistic.

In this paper we propose the Generalized Multiprocessor Periodic Resource model (GMPR) that is strictly superior to the MPR model without requiring a too detailed description. We describe a method to generate the interface from the application specification. All these methods have been implemented in Matlab routines that are publicly available.

## 1. INTRODUCTION

Reusing application code is a key design principle to shorten the overall design time. According to this design methodology, software components are designed in isolation, possibly by different developers. Then, during the integration phase,

all components are bound to the same execution platform. Clearly, the integration must be performed in such a way that the properties of components are preserved even after the composition is made.

In real-time systems, the key property that has to be preserved during the integration phase is time predictability: a real-time application that meets all its deadlines when designed in isolation, should also meet all deadlines when it is integrated with other applications on the same system. This property is often guaranteed by introducing an *interface* between the application and the physical platform. Then the application is guaranteed over the interface, and the physical platform must provide a *virtual platform* that conforms with the interface. The scheduling problem over a virtual platform is often called *hierarchical scheduling* problem. In fact, the application tasks may contain an entire application in a hierarchical fashion. The benefit of using an interface-based approach is significant: during the design phase the interface of a virtual platform is designed such that the timing requirements of the application are met; during the integration phase the interfaces of all applications are combined over the same physical platform.

Typically, interfaces that allow composition of real-time components provide details about the amount of computation that can be provided by the virtual platform. This information can be provided with a varying degree of detail. For example, a very simple interface of a virtual processor can be just the fraction of provided time.

With the broad diffusion of multiprocessors, hierarchical scheduling problems have recently been considered over execution platforms that provide parallelism. The formulation of interface models for multiprocessor, however, requires the introduction of a new dimension: the *degree of parallelism*. This extra characteristic of the interface makes the problem to be addressed more challenging.

The problem in selecting the appropriate interface is to find the most opportune balance between accuracy and simplicity of the interface. In this paper we propose a simple interface that is a generalization of a previously proposed one [20]. To better describe the context of our contribution, next we describe the most relevant related works.

### 1.1 Related works

The problem of composing real-time applications is certainly not new. There actually have been numerous contributions in this area. Being fully aware of the impossibility to provide a full coverage of the topic, we describe in this section the works that, to our best knowledge, are more related to ours.

One of the first papers to address the isolation of applications using *resource reservations* was published in 1993 by Parekh and Gallager [19], who introduced the Generalized Processor Sharing (GPS) algorithm to share a fluid resource according to a set of weights. Mercer *et al.* [17] proposed a more realistic approach where a resource can be allocated based on a required budget and period. Stoica *et al.* [22] introduced the Earliest Eligible Virtual Deadline First (EEVDF) for sharing the computing resource. Deng and Liu [6] achieved the same goal by introducing a two-level scheduler (using EDF as a global scheduler) in the context of multi-application systems. Kuo and Li [12] extended the approach to a Fixed Priority global scheduler. Kuo *et al.* [13] extended their previous work [12] to multiprocessors. However, they made very stringent assumptions (such as no task migration and period harmonicity) that restricted the applicability of the proposed solution.

Moir and Ramamurthy [18] proposed a hierarchical approach, where a set of P-fair tasks can be scheduled within a time partition provided by another P-fair task (called “supertask”) acting as a server. However, the solution often requires the weight of the supertask to be higher than the sum of the weights of the served tasks [11].

Many independent works proposed to model the service provided by a uniprocessor through a supply function. Feng and Mok introduced the bounded-delay resource partition model [8]. Almeida *et al.* [1] provided timing guarantees for both synchronous and asynchronous traffic over the FTT-CAN protocol by using hierarchical scheduling. Lipari and Bini [15] derived the set of virtual processors that can feasibly schedule a given application. Shin and Lee [21] introduced the periodic resource model also deriving a utilization bound. Easwaran *et al.* [7] extended this model allowing the server deadline to be different than the period. Fisher and Dewan [9] proposed an approximation algorithm to test the schedulability of a task set over a periodic resource.

Recently, some authors have addressed the problem of how to specify the application interface for an application to be executed on multiprocessor systems, and provide appropriate schedulability analysis to check if the application is schedulable on the interface.

Leontyev and Anderson [14] proposed to use only the overall bandwidth requirement  $w$  as interface for soft real-time applications. The authors propose to allocate a bandwidth requirement of  $w$  onto  $\lfloor w \rfloor$  dedicated processors, plus an amount of  $w - \lfloor w \rfloor$  provided by a periodic server globally scheduled onto the remaining processors. An upper bound of the tardiness of tasks scheduled on such interface was provided.

Shin *et al.* [20] proposed the multiprocessor periodic resource model (MPR) that specifies a period, a budget and maximum level of parallelism of the resource provisioning. Since our work is a generalization of the MPR, in Section 2.2 we describe it in greater detail.

Chang *et al.* [5] proposed to partition the resource available from a multiprocessor by a static periodic scheme. The amount of resource is then provided to the application through a contract specification.

Bini *et al.* [4] proposed the Parallel Supply Function (PSF) interface of a virtual multiprocessor. This interface can be seen as a generalization of any possible interface model and it is the most resource-efficient. However, it is not investigated the assignment of the interface parameters that guarantee a

real-time application.

Lipari and Bini [16] described an entire framework for composing real-time applications running over a multiprocessor. However their proposed interface was extremely simple.

## 1.2 Contributions of the paper

The contributions of the paper are highlighted in **bold** in the paragraph below.

In Section 2 we recall some previous interface models such as the Parallel Supply Function (PSF) and the Multiprocessor Resource Model (MPR). In Section 3 we provide an example illustrating that the MPR interface may require some more resource than actually needed. Section 4 introduces **the Generalized Multiprocessor Periodic Resource model (GMPR)**. We also show **how to compute the PSF interface of a GMPR interface**. In Section 5 a **schedulability condition over a GMPR interface** is presented. This condition, inspired by the one proposed by Bertogna, Cirinei and Lipari [3], can be applied to several different policies for scheduling the application tasks. In Section 6 we show **how to design a GMPR interface that requires the minimal resource and can guarantee a real-time application** specified by a set of sporadic tasks with deadline. In Section 7 we briefly describe the problem of **scheduling the GMPR interfaces**. Finally, in Section 8 we report some simulations.

## 2. BACKGROUND

As our work is tightly tied to several previous works, in this section we briefly review concepts and notations we borrow.

### 2.1 The Parallel Supply Function resource model

The parallel supply function (PSF) was proposed by Bini *et al.* [4] to characterize the resource allocation in hierarchical systems executed upon a multiprocessor platform. This interface introduces the minimum possible pessimism in abstracting the amount of resource provided by a platform. As a drawback it is certainly quite complicated to be handled. Without entering all the details of the definition (that can indeed be found in [4]), we recall here the basic concepts.

**DEFINITION 1.** *The Parallel Supply Function interface (PSF) of a multiprocessor resource is composed by the set of functions  $\{Y_k\}_{k=1}^m$ , where  $m$  is the number of virtual processors and  $Y_k(t)$  is the minimum amount of resource provided in any interval of length  $t$  with a parallelism of at most  $k$ . The function  $Y_k(t)$  is called the level- $k$  parallel supply function.*

To clarify this definition we propose an example. Suppose that in the interval  $[0, 11]$  the resource is provided by three processors according to the schedule drawn in gray in Figure 1.

In this case  $Y_1(11) = 10$  because there is always at least one processor available in  $[0, 11]$  except in  $[8, 9]$ . Then  $Y_2(11) = 16$ ; that is found by summing up all the resource except one with parallelism 3 (provided only in  $[4, 5]$ ). Finally,  $Y_3(11) = 17$ ; that is achieved by summing all the resources provided in  $[0, 11]$ . In general, the parallel supply functions are computed also by sliding the time window of length  $t$  and

Figure 1: From a resource schedule to the PSF.

by searching for the most pessimistic scenario of resource allocation. This minimization is somehow equivalent to the one performed on uni-processor hierarchical scheduling [8, 15, 21].

Although the PSF interface is capable to tightly capture the amount of provided resource, its complexity prevents a straightforward application. It is unclear how a PSF interface should be designed so that an application is guaranteed. On the other extreme, next we report a very simple interface model.

## 2.2 The MPR interface model

The multiprocessor periodic resource model (MPR) [20] is one of the simplest resource abstractions. Its definition is as follows.

DEFINITION 2. Let us set 0 as the time instant when the resource is firstly supplied. A Multiprocessor Periodic Resource model (MPR) is modeled by a triplet

$$\langle \Pi, \Theta, m \rangle,$$

where  $\Pi$  is the time period and  $\Theta$  is the minimal amount of supply provided within each interval  $[k\Pi, (k+1)\Pi)$ , with  $k \in \mathbb{N}$ , by at most  $m$  processors. Often we also say that  $m$  is the concurrency (or the degree of parallelism) of the interface. The utilization of a MPR interface is the ratio  $\frac{\Theta}{\Pi}$ . In this work we assume that  $\Pi$  and  $\Theta$  are positive integers.

Since a MPR interface fixes only the aggregated parameters  $\Pi$ ,  $\Theta$  and  $m$  of the supply pattern, any feasible allocation of  $\Theta$  resource units per time period  $\Pi$  should preserve the schedulability of the underlying task set. In Figure 2, we show an example of the resource allocation of a MPR interface  $\langle 7, 14, 3 \rangle$ . It can be noted that in each period the allocation patterns may be different.

Figure 2: Graphical interpretation of a MPR model

As the task set should be guaranteed under any possible resource allocation scenario, it is then necessary to find the worst-case supply allocation of the MPR. As shown by Shin *et al.* [20], the worst-case scenario is the one depicted in Figure 3. Since the PSF can be computed for any possible resource allocation scheme, we can compute it also for the MPR interface. At the bottom of Figure 3 we show the

Figure 3: The worst-case supply allocation under the MPR model

$i$	$C_i$	$T_i$	$D_i$
1	6	40	40
2	13	50	50

4	27	70	70

Table 1: An example of a task set.

level- $m$  parallel supply function  $Y_m(t)$  of a MPR interface. More details about this computation can be found in [20].

The computation of the PSF interface  $\{Y_k\}_{k=1}^m$  of a MPR enables the adaptation of schedulability tests developed over a PSF interface to a MPR interface. More details about the schedulability test will be provided in Section 5.

## 3. MOTIVATION FOR EXTENDING THE MPR INTERFACE

In this section we motivate the necessity for extending the MPR interface model. By proposing this extension we aim at minimizing the overall resource abstracted in the MPR interface required to guarantee the schedulability of the underlying task set.

Assume that a MPR interface  $\langle \Pi, \Theta, m \rangle$  abstracts the processing requirements of a real-time tasks set. By definition, a MPR interface specifies only the aggregated supply  $\Theta$ . However, we show below that, preserving the schedulability, our approach allows to reduce the value of the required resource in the abstraction by further detailing its allocation in processors.

As an example, consider the tasks set with the parameters reported in Table 1, to be scheduled by global EDF (GEDF) over the MPR interface. In this table, tasks are reported in rows and for each task we denote its execution time by  $C_i$ , its period by  $T_i$ , and its deadline by  $D_i$ .

After setting the period of the interface  $\Pi = 15$ , we com-

pute a MPR interface  $\langle \Pi, \Theta, m \rangle$  that can guarantee the task set. To check the schedulability, we reuse the PSF-based test proposed by Bini *et al.* [4] (see Section 5 for details). Based on this test, we determine that the minimal feasible value of resource to guarantee the schedulability is  $\Theta = 39$ . Notice that there is quite a significant gap between the utilization of the interface  $\frac{\Theta}{\Pi} = 2.6$  and the utilization of the task set  $\sum_i \frac{C_i}{T_i} = 1.28$ .

As we will show in greater detail in the next sections, our proposed interface requires only 34 resource units per period, meaning that it has a utilization of  $\frac{34}{15} = 2.267$ .

#### 4. THE GENERALIZED MULTIPROCESSOR PERIODIC RESOURCE MODEL

As highlighted in Section 3, the MPR resource model can lead to some waste of computational resources. In this section we describe a resource model that is better capable to tightly capture the resource requirement of the underlying task set.

**DEFINITION 3.** *Let us set 0 as the time instant when the resource is firstly supplied. We define the Generalized Multiprocessor Periodic Resource model interface (GMPR) as*

$$\langle \Pi, \{\Theta_1, \dots, \Theta_m\} \rangle,$$

where  $\Pi$  is the time period,  $\Theta_k$  is the minimal supply provided by at most  $k$  processors. The period  $\Pi$  and all the values of  $\Theta_k$  are positive integers. Also, the values of  $\Theta_k$  must satisfy the following constraints for any  $k = 1, \dots, m$  (for notational convenience we denote  $\Theta_0 = 0$ ):

$$\begin{aligned} 0 < \Theta_{k+1} - \Theta_k &\leq \Pi \\ \Theta_{k+1} - \Theta_k &\leq \Theta_k - \Theta_{k-1} \end{aligned} \quad (1)$$

The  $(k+1)$ th virtual processor provides  $\Theta_{k+1} - \Theta_k$  supply units every period  $\Pi$ . Thus, we impose a strict constraint  $\Theta_{k+1} > \Theta_k$  to avoid the case when no real supply is provided by the  $(k+1)$ th processor. At the same time, the constraint  $\Theta_{k+1} - \Theta_k \leq \Pi$  reflects the fact that a single virtual processor is not capable to provide more than  $\Pi$  supply units within an interval of  $\Pi$ . The last constraint  $\Theta_{k+1} - \Theta_k \leq \Theta_k - \Theta_{k-1}$  aims to put some determinism into the supply allocation, meaning that the  $(k+1)$ th processor does not provide a larger supply than the  $k$ th processor.

By definition, a GMPR interface is a guarantee for the schedulability of a task set, meaning that any feasible supply allocation compliant to the GMPR model will result in meeting all the deadlines under the employed scheduling policy.

The GMPR model  $\langle \Pi, \{\Theta_1, \dots, \Theta_m\} \rangle$  is a generalization of the MPR  $\langle \Pi, \Theta, m \rangle$ , where  $\Theta = \Theta_m$ .

##### 4.1 The Parallel Supply Functions of GMPR

To be able to borrow the schedulability tests developed over the PSF interface [4], we introduce the computation of the parallel supply functions  $Y_k(t)$  for the GMPR specification.

Following a similar reasoning as for the MPR in [20], the worst-case supply pattern for the GMPR model is as depicted in Figure 4. Let us introduce an auxiliary function  $\text{supply}_k(t)$  to quantify the supply provided by the first  $k$  concurrency levels within the time interval  $[0, t]$ . According to

**Figure 4: The worst-case supply allocation under the GMPR model**

the worst-case scenario of Figure 4, it follows that

$$\begin{aligned} \text{supply}_k(t) = & \sum_{\ell=1}^k \min \{t, \Theta_\ell - \Theta_{\ell-1}\} + \left\lfloor \frac{(t - \Pi)_0}{\Pi} \right\rfloor \Theta_k + \\ & + \sum_{\ell=1}^k (((t - \Pi)_0 \bmod \Pi) - (\Pi - (\Theta_\ell - \Theta_{\ell-1})))_0 \end{aligned}$$

where  $(x)_0$  denotes  $\max(x, 0)$ . Then, from the definition of the PSF function, it follows that

$$Y_k(\Delta t) = \min_{\forall t \geq 0} (\text{supply}_k(t + \Delta t) - \text{supply}_k(t))$$

Now we make the classic observation that a minimum of the previous expression must always occur at  $t$  equal to some instant of termination of a resource supply. These candidate time instants are denoted in Figure 4 by  $t_i^*$ . Hence the minimum can be computed over  $T^* = \{t_1^*, t_2^*, \dots, t_m^*\}$  without making any optimistic assumption. Therefore the PSF of a GMPR can be computed by

$$Y_k(\Delta t) = \min_{t \in T^*} (\text{supply}_k(t + \Delta t) - \text{supply}_k(t)). \quad (2)$$

We also observe that the  $k$ -th function of the PSF can be upper bounded by the following simple linear function

$$Y_k(t) \leq \bar{Y}_k(t) = \frac{\Theta_k}{\Pi} t. \quad (3)$$

This upper bound will be exploited in Section 6 to reduce the complexity of the algorithm to compute the GMPR interface of an application composed by a set of tasks.

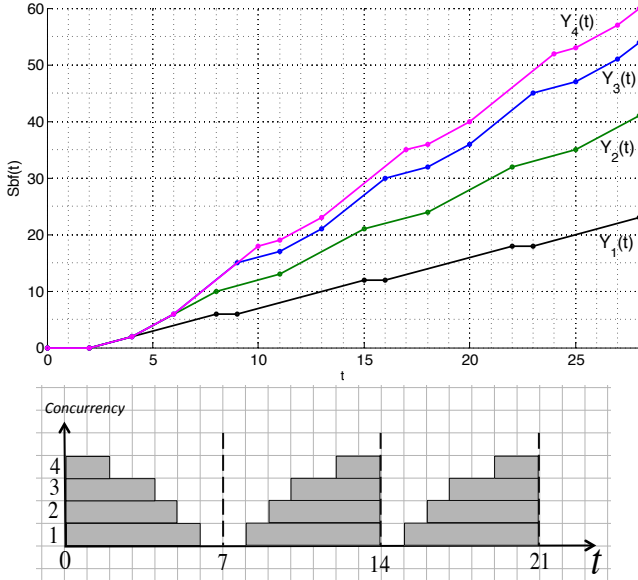

As an example, in Figure 5 we illustrate the 4 parallel supply functions  $\{Y_k(t)\}_{k=1}^4$  of the GMPR interface  $\langle 7, \{6, 11, 15, 17\} \rangle$ . At the bottom of the figure we also represent the worst-case resource supply that originates the parallel supply functions.

#### 5. SCHEDULABILITY OVER GMPR

The GMPR interface describes the amount of computing resources provided to an application. We can then formulate a schedulability test over the GMPR.

Let us consider a task set  $\mathcal{T}$  composed by the tasks  $\tau_1, \dots, \tau_n$ . Each task  $\tau_i$  is modeled by its computation time  $C_i$ , period  $T_i$ , and deadline  $D_i$ .

As schedulability test for the application, we choose the extension of the test by Bertogna *et al.* [3] to the PSF interface developed in [4]. We choose this condition because it applies to several different application schedulers such as global EDF or global FP, although it assumes constrained

**Figure 5: The PSF (top) and the worst-case supply pattern (bottom) of the GMPR interface  $\langle 7, \{6, 11, 15, 17\} \rangle$ . The bold points indicate the slope change of the PSF functions.**

deadline tasks, i.e. for all tasks  $\tau_i$ ,  $D_i \leq T_i$ . While choosing other tests is possible [2], the proposed formulation has the advantage of highlighting the constraint on the interface. Thanks to the lossless transformation of a GMPR interface into a PSF (see Section 4.1), we can apply directly the schedulability condition developed over PSF. Below we report, for completeness, the schedulability condition in the simpler expression proposed by Lipari and Bini [16].

**THEOREM 1** (THEOREM 1 IN [16]). *A set of tasks  $\{\tau_i\}_{i=1}^n$  is schedulable on a resource modeled by the PSF  $\{Y_k\}_{k=1}^m$ , if*

$$\bigwedge_{i=1, \dots, n} \bigvee_{k=1, \dots, m} k C_i + W_i \leq Y_k(D_i), \quad (4)$$

where  $W_i$  is the maximum interfering workload that can be experienced by task  $\tau_i$  in the interval  $[0, D_i]$ , defined as

$$W_i = \sum_{j=1, j \neq i}^n \left\lfloor \frac{D_i}{T_j} \right\rfloor C_j + \min \left\{ C_j, D_i - \left\lfloor \frac{D_i}{T_j} \right\rfloor T_j \right\}, \quad (5)$$

if the application tasks are scheduled by global EDF. Instead if the application tasks are scheduled by global FP

$$W_i = \sum_{j \in \text{hp}(i)} W_{ji}, \quad (6)$$

where  $\text{hp}$  denotes the set of indices of tasks with higher priority than  $i$ , and  $W_{ji}$  is the amount of interfering workload caused by  $\tau_j$  on  $\tau_i$ , that is

$$W_{ji} = N_{ji} C_j + \min \{ C_j, D_i + D_j - C_j - N_{ji} T_j \} \quad (7)$$

with  $N_{ji} = \left\lfloor \frac{D_i + D_j - C_j}{T_j} \right\rfloor$ .

Below we exploit such a schedulability condition to compute the GMPR parameters  $\Theta_1, \dots, \Theta_m$  for a given task set.

## 6. THE GMPR COMPUTATION

When an application  $\mathcal{T} = \{\tau_1, \dots, \tau_n\}$  is given, it is of key importance to select the interface that can guarantee the timing constraints of the application and, at the same time, requires the minimal amount of resource. Hence, in this section we describe an algorithm to generate a GMPR interface  $\langle \Pi, \{\Theta_k\}_{k=1}^m \rangle$  of a given sporadic task set  $\{\tau_1, \dots, \tau_n\}$ . As schedulability condition, we choose the one of Theorem 1.

To compute a GMPR interface, we follow a similar approach as the one proposed by Shin *et al.* [20] to generate a MPR interface. First, the period  $\Pi$  of the GMPR interface is set by the system designer considering such aspects as preemption overheads and etc. Then for a fixed value of  $m$  (the parallelism of the interface) not smaller than  $\left\lceil \sum_i \frac{C_i}{T_i} \right\rceil$ , our algorithm finds the values of cumulative resource  $\Theta_m, \dots, \Theta_1$  such that the computing resource is minimized.

Rather than simply (but in a very time consuming way) enumerating all possible values of  $\Theta_k$  as proposed by Shin *et al.* [20], we exploit the condition on  $\Theta_k$  that follows from the linear upper bound of Eq. (3). In fact, from (4) and (3) it follows that any feasible values of  $\Theta_1, \dots, \Theta_m$  must also be such that

$$\bigwedge_{i=1, \dots, n} \bigvee_{k=1, \dots, m} k C_i + W_i \leq \frac{\Theta_k}{\Pi} D_i,$$

from which we have the following condition on all  $\Theta_k$

$$\bigwedge_{i=1, \dots, n} \bigvee_{k=1, \dots, m} \Theta_k \geq \left\lceil \frac{\Pi}{D_i} (k C_i + W_i) \right\rceil, \quad (8)$$

by also accounting for the integrality of  $\Theta_k$ .

The necessary condition of Eq. (8) can be exploited to reduce significantly the search space. For any task  $\tau_i$ , let us define the vector  $v_i = [v_i^1, \dots, v_i^m]$  as

$$v_i = \left[ \left\lceil \frac{\Pi}{D_i} (C_i + W_i) \right\rceil, \dots, \left\lceil \frac{\Pi}{D_i} (m C_i + W_i) \right\rceil \right]. \quad (9)$$

The reduced search space is computed by Algorithm 1. We illustrate its execution by an example.

Figure 6: Illustration of the search space reduction.

$i$	$C_i$	$T_i$	$D_i$	$W_i$ (GEDF)
1	12	40	40	38
2	23	50	50	37
3	15	60	60	57

Table 2: An example of a task set.

Let us assume to have 4 tasks and  $m = 2$ . Let us also assume that the values of  $v_1, v_2, v_3, v_4$  are the ones depicted in Figure 6. In the first run of the outer loop (lines 3–16) the set  $S_\Theta$  is empty. Then  $v_1$  is simply added to  $S_\Theta$ . When  $i = 2$ , none of the two conditions of lines 7, 11 are true, hence  $v_2$  is also added to  $S_\Theta$ . When  $i = 3$ , the condition at line 11 is true when  $v = v_2$ . Hence,  $v_2$  can be removed from  $S_\Theta$  because the schedulability condition (8) for  $i = 3$  is stricter than the one for  $i = 2$ . Finally, when  $i = 4$  the condition at line 7 is true when  $v = v_3$  and then the vector  $v_4$  can be ignored. It can be noted that Algorithm 1 for determining the reduced search space has complexity  $o(n^2m)$  that is polynomial. Moreover its result does not depend on the order in which the vectors  $v_i$  are visited.

Once  $S_\Theta$  is determined by Algorithm 1, the GMPR generation process is then based on searching the assignment that requires the minimum amount of resource among all values  $(\Theta_1, \dots, \Theta_m)$  satisfying the following constraints

$$\forall v \in S_\Theta \exists k = 1, \dots, m, \quad \Theta_k \geq v^k \quad (10)$$

$$\Theta_1 \leq \Pi \quad (11)$$

$$\forall k = 1, \dots, m-1 \quad \Theta_{k+1} - \Theta_k \leq \Theta_k - \Theta_{k-1} \quad (12)$$

$$\Theta_m \geq \Theta_{m-1} \quad (13)$$

where Condition (10) follows from (8), while Conditions (11)–(13) follow from Definition 3 of the GMPR interface.

### 6.1 Example of GMPR computation

We illustrate the algorithm by an example. To ease the graphical representation of the concept we analyze the case of  $m = 2$ .

Let us consider the task set  $\mathcal{T}$  with the parameters reported in Table 2. If the task set is scheduled by GEDF over the interface then, from Eq. (5), we can compute the quantities  $W_i$  that are reported in the last column of the table.

We set  $\Pi = 15$  and  $m = 2$ . From (9), we have that

$v_1 = (19, 24)$ ,  $v_2 = (18, 25)$ , and  $v_3 = (18, 22)$ . However, by executing the REDUCESEARCHSPACE algorithm we find that the vector  $v_3$  can be ignored, since the condition (8) with  $i = 3$  is implied by the others. Hence  $S_\Theta = \{v_1, v_2\}$ .

The search space is depicted in Figure 7, in gray. Figure 7(a) shows the feasible values of  $(\Theta_1, \Theta_2)$  by only considering the constraints (11)–(13) that follow from Definition 3 of GMPR. In Figure 7(b) we show how much the search space is shrunk by enforcing the necessary condition of (8). Among the possible selections of  $(\Theta_1, \Theta_2)$ , in Figure 7(b), we also show, which ones are capable to guarantee the deadline constraints of the task set (denoted by a black dot) and which ones are not (denoted by a red cross). Hence the GMPR interface that consumes the minimal amount of resource is  $(15, \{15, 26\})$ . It is also interesting to observe that in this example the best MPR interface was  $(15, 27)$  that consumes one unit of resource more than the best GMPR.

## 7. SCHEDULABILITY ANALYSIS OF GMPR INTERFACES

Once the processing requirements of each component in a hierarchical system are abstracted using GMPR interfaces, they should be scheduled upon a hardware platform. For this purpose we introduce a notion of interface tasks. An interface task set for a GMPR interface  $\langle \Pi, \{\Theta_k\}_{k=1}^m \rangle$  is defined as

$$\mathcal{T}' = \{\tau'_1 = (C'_1, \Pi), \dots, \tau'_m = (C'_m, \Pi)\},$$

where  $C'_i = (\Theta_k - \Theta_{k-1})$ . We recall that we set  $\Theta_0 = 0$  for notational convenience. It is easy to see that the overall processing requirement of  $\mathcal{T}'$  is  $\Theta_m$  per period  $\Pi$  as  $\sum_{k=1}^m C'_k = \Theta_m$ . Therefore, we propose to schedule GMPR interfaces by transforming each one into interface tasks and to schedule the resulting union of these periodic tasks instead.

The notion of interface tasks supports another important property for hierarchical systems, which is *composability*: by

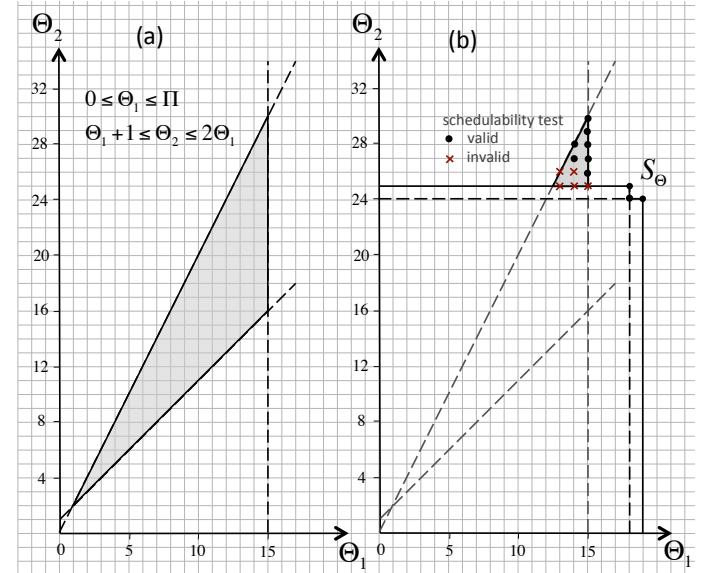

Figure 7: The example of a GMPR interface computation

the given GMPR interfaces of child components we can compute a GMPR interface of a parent component.

## 8. IMPLEMENTATION AND SIMULATIONS

The algorithm for generating GMPR interfaces is implemented in Matlab and it is available at <https://sites.google.com/site/artemurmyakov/home/papers>.

### 8.1 Task set generation

To generate a task set  $\mathcal{T} = \{\tau_i = (C_i, T_i)\}$  the user specifies the total task set utilization  $U_{\mathcal{T}}$ , an upper bound for individual task utilizations  $U_{max}$ , and the ratio of maximum to minimum periods  $\frac{T_{max}}{T_{min}}$ . The number of tasks in  $\mathcal{T}$  is not fixed *a priori*.

The generation of  $\mathcal{T}$  is based on distributing the total utilization  $U_{\mathcal{T}}$  between the tasks. So, the utilization  $u_i$  of a task  $\tau_i$  is randomly selected from the range  $(0; U_{max})$  and the overall utilization of the remaining tasks to be generated, denoted as  $U_r$ , is reduced by the value of  $u_i$ . Once  $U_r \leq U_{max}$ , the last task  $\tau_n$  is created with  $u_n = U_r$ . Thus, the total utilization of  $\mathcal{T}$  is  $U_{\mathcal{T}}$ .

As a next step we randomly select the value of  $T_{min}$  from some predefined range and compute  $T_{max} = T_{min} \frac{T_{max}}{T_{min}}$ . Then the period  $T_i$  of each task  $\tau_i$  is randomly taken from the range  $[T_{min}; T_{max}]$ , and finally its execution time is computed as  $C_i = u_i T_i$ .

### 8.2 Experiments

In the performed experiments, we compared the utilization of the interface  $\frac{\Theta_m}{\Pi}$  as the interface period  $\Pi$  varies. For all the five experiments reported below we plot the interface utilization of GMPR and MPR for both FP and EDF scheduling policies. All the experiments share the following characteristics:

- each experiment was conducted by randomly generating 200 task sets,
- the minimum task period was random extracted between 20 and 40, and
- the total utilization of tasks was set equal to  $U = 1.5$ .

In the first experiment, reported in Figure 8, we set the number of processors  $m = 4$ , the maximum utilization of a single task equal to  $U_{max} = 0.4$ , and the ratio between the maximum and minimum task periods  $\frac{T_{max}}{T_{min}} = 1.5$ . It can be observed that the gain in term of overall resource usage of GMPR w.r.t. MPR is in the order of 5%, when tasks are scheduled by FP (blue plots) and around 10% when tasks are scheduled by EDF (black plots). Notice that the gain of GMPR increases with the period of the interface.

To explore the dependency on the weight of the individual tasks, in the second experiment we set  $U_{max} = 0.7$ , keeping the number of processors  $m = 4$  and the ratio  $\frac{T_{max}}{T_{min}} = 1.5$ . Results are shown in Figure 9. With these settings, the gain of GMPR compared to MPR is in the order of 10% for FP (blue plots) and 15% for EDF (black plots). The trend with an increasing gain as a function of  $\Pi$  is confirmed.

In the third and fourth experiments (depicted in Figures 10, 11), we also investigate the dependency on the task periods by setting  $\frac{T_{max}}{T_{min}} = 10$  and  $\frac{T_{max}}{T_{min}} = 100$  correspondingly, keeping  $m = 4$  and  $U_{max} = 0.4$ . An interesting phenomenon that we observe in this case is that FP requires a

Figure 8: Case (a):  $m = 4$ ,  $U_{max} = 0.4$ ,  $\frac{T_{max}}{T_{min}} = 1.5$ .

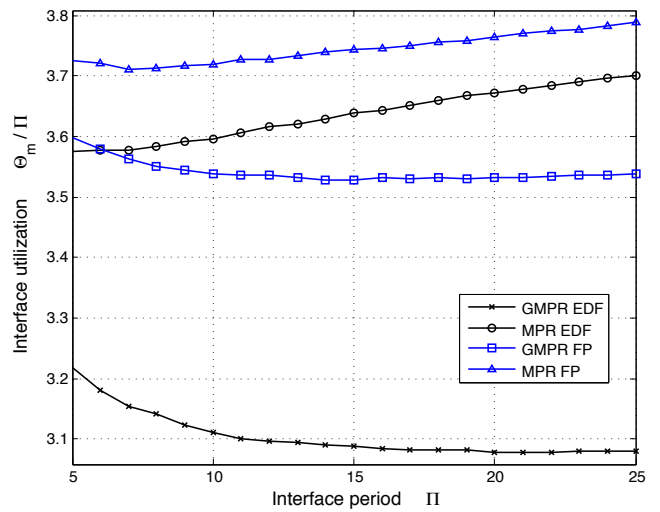

Figure 9: Case (b):  $m = 4$ ,  $U_{max} = 0.7$ ,  $\frac{T_{max}}{T_{min}} = 1.5$ .

smaller amount of resource w.r.t. EDF. This has to be explained with the nature of the schedulability test. The gains of GMPR over MPR are in the same order of magnitude as in the previous experiments.

In the last experiment we analyze the dependency on the number of processors by setting  $m = 5$ , and keeping  $\frac{T_{max}}{T_{min}} = 100$ ,  $U_{max} = 0.4$ . The results are depicted in Figure 12. It can be clearly seen that the gain of GMPR compared to MPR increases as  $m$  increases.

In all experiments we can observe a quite significant distance between the interface utilization, always around 3 and the task set utilization that is 1.5. This waste of resource, however, does not depend on the particular interface selected. It has instead to do with the pessimism introduced by the schedulability tests. We believe that if the schedulability tests can be tightened, for example by using more sophisticated tests that better account for the amount of task interference [10], then the loss due to the interface can certainly be reduced as well.

Figure 10: Case (c):  $m = 4$ ,  $U_{\max} = 0.4$ ,  $\frac{T_{\max}}{T_{\min}} = 10$ .

Figure 11: Case (d):  $m = 4$ ,  $U_{\max} = 0.4$ ,  $\frac{T_{\max}}{T_{\min}} = 100$ .

## 9. CONCLUSIONS

Motivated by the need to save resource, we introduced the Generalized Multiprocessor Periodic Resource model. Since GMPR is a generalization of MPR, it can consume at most as much as MPR. We provided a schedulability algorithm for task sets scheduled over GMPR by FP or EDF. We also provided an algorithm that is capable to select the minimal interface parameters for a given set of tasks.
